## Abstract

This paper introduces a measure for zigzagging strength and a minimal zigzagging direction. Based on this, a new nonlinear conjugate gradient (CG) method is proposed that works with line searches not satisfying the Wolfe condition. Global convergence to a stationary point is proved for differentiable objective functions with Lipschitz continuous gradient, and global linear convergence if this stationary point is a strong local minimizer. For approximating a stationary point, an  $\mathcal{O}(\varepsilon^{-2})$  complexity bound is derived for the number of function and gradient evaluations. This bound improves to  $\mathcal{O}(\log \varepsilon^{-1})$  for objective functions having a strong minimizer and no other stationary points. For strictly convex quadratic functions in  $n$  variables, the new method terminates in at most  $n$  iterations. Numerical results on the unconstrained CUTEst test problems suggest that the new method is competitive with the best nonlinear state-of-the-art CG methods proposed in the literature.

# 1 Introduction

This paper discusses a new nonlinear conjugate gradient (CG) method for the unconstrained optimization problem

$$\begin{aligned} \min & f(x) \\ \text{s.t. } & x \in \mathbb{R}^n, \end{aligned} \quad (1)$$

where  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  is continuously differentiable with Lipschitz continuous gradient.

## 1.1 Related work

The unconstrained optimization problem has a very long history which we do not trace here; see, instead, the books by Fletcher [13] or Nocedal and Wright [31]. Here, we only discuss the state-of-the-art concerning nonlinear conjugate gradient methods used in this context.

### 1.1.1 Standard convergence theory and complexity

To obtain complexity results or global convergence an optimization method, we make the following two assumptions:

(A1) The function  $f$  is bounded below, i.e.,

$$\underline{f} := \inf_{x \in \mathbb{R}^n} f(x) > -\infty. \quad (2)$$

(A2) The function  $f$  is continuously differentiable on  $\mathbb{R}^n$ , and its gradient  $g(x) = f'(x)^T$  is Lipschitz continuous with Lipschitz constant  $\bar{\gamma}$ , i.e.,

$$\|g(x) - g(x')\|_* \leq \bar{\gamma} \|x - x'\| \quad \text{with } \bar{\gamma} > 0. \quad (3)$$

Here  $\|\cdot\|$  is an arbitrary norm and  $\|\cdot\|_*$  is its dual norm, defined by

$$\|y\|_* := \sup\{y^T x \mid \|x\| \leq 1\}.$$

They satisfy the **generalized Cauchy–Schwarz inequality**

$$|y^T s| \leq \|y\|_* \|s\| \quad \text{for } s, y \in \mathbb{R}^n.$$

Warth and Werner [39] call a line search **efficient** if it always returns step sizes satisfying

$$(f(x) - f(x + \alpha p)) \frac{\|p\|^2}{(g(x)^T p)^2} \geq \zeta, \quad (4)$$

where  $\zeta$  is a fixed positive real number, and prove the following basic convergence result (their Lemma 2.1 and Satz 2.2).

For any sequence  $x^0, x^1, x^2, \dots$  of feasible points and  $\ell = 0, 1, 2, \dots$ , we write

$$\begin{aligned} f_\ell &:= f(x^\ell), \quad g^\ell := g(x^\ell), \\ s^\ell &:= x^{\ell+1} - x^\ell, \quad y^\ell := g^{\ell+1} - g^\ell. \end{aligned} \quad (5)$$

**Theorem 1** Suppose that (A1) and (A2) hold. Given an optimization method that uses search directions satisfying the **Zoutendijk condition**

$$\sum_{\ell} \left( \frac{-g(x^\ell)^T p^\ell}{\|g(x^\ell)\|_* \|p^\ell\|} \right)^2 = \infty \quad (6)$$

and computes its points by

$$x^{\ell+1} = x^\ell + \alpha_\ell p^\ell, \quad \alpha_\ell > 0, \quad (7)$$

where  $p^\ell$  is a descent direction. If the line searches are efficient then

$$\lim_{\ell \rightarrow \infty} f(x^\ell) = f(\hat{x}), \quad \inf_{\ell} \|g^\ell\|_* = 0. \quad (8)$$

If the Zoutendijk condition does not hold, there is no global convergence for any gradient-based descent method. ([39, Satz 2.2]).

We call a point  $\hat{x} \in \mathbb{R}^n$  a **strong local minimizer** of  $f$  if  $f$  is twice continuously differentiable in a neighborhood of  $\hat{x}$ , the gradient  $g(\hat{x})$  of  $f$  at  $\hat{x}$  vanishes, and the Hessian  $G(\hat{x})$  of  $f$  at  $\hat{x}$  is positive definite.

The following result is a consequence of Theorem 1.

**Theorem 2** Under the same assumptions, if the  $x^\ell$  converge to a strong local minimizer  $\hat{x}$  and the **bounded angle condition**

$$\frac{(g^\ell)^T p^\ell}{\|g^\ell\|_* \|p^\ell\|} \leq -\delta < 0 \quad \text{for } \ell = 1, 2, \dots \quad (9)$$

holds, there are constants  $q \in ]0, 1[$  and  $c > 0$  such that

$$\|x^\ell - \hat{x}\| \leq cq^\ell, \quad \|g^\ell\|_* \leq \bar{\gamma}cq^\ell \quad \text{for all } \ell \geq 0. \quad (10)$$

**Proof** Clearly, the bounded angle condition implies the Zoutendijk condition. The remainder of the proof can be easily followed from [38, Theorem 2.2.8].  $\square$

Linear convergence by itself does not imply a complexity statement since it is unclear how many function values are used in each line search. Bounding this number to get a good complexity result (see Theorem 8) is an essential part of the analysis of our new method.

Recently, Neumaier and Kimiaei [30] proposed a new line search method CLS, which guarantees that the sufficient descent condition

$$\mu(\alpha)|\mu(\alpha) - 1| \geq \beta, \quad \text{with fixed } \beta > 0 \quad (11)$$

holds for the Goldstein quotient (Goldstein [15])

$$\mu(\alpha) := \frac{f(x + \alpha p) - f(x)}{\alpha g(x)^T p} \quad \text{for } \alpha > 0. \quad (12)$$

In the first iteration, if  $\mu(\alpha) < 1$  holds, CLS computes the step size

$$\hat{\alpha} = \frac{\alpha}{2(1 - \mu(\alpha))} \quad (13)$$

to ensure termination with at most two function evaluations when  $f$  is almost quadratic, i.e., a twice continuously differentiable function close to a minimizer. Until (11) holds, CLS performs a simple bisection scheme since  $f$  is far from quadratic and bounded. CLS performs either interpolation with (13), or extrapolation with a constant factor  $q > 1$ , to obtain a bracket  $[\underline{\alpha}, \bar{\alpha}]$  with  $\underline{\alpha} > 0$  and  $\bar{\alpha} < \infty$ . Once CLS finds such a bracket, the geometric mean of  $\underline{\alpha}$  and  $\bar{\alpha}$  is chosen as a new step size in the next iteration. After CLS terminates with  $\alpha > 0$  satisfying (11), then the condition (4) is satisfied for any step size  $\alpha'$  with  $f(x + \alpha' p) \leq f(x + \alpha p)$  ([30, Theorem 3.1]).

For any descent optimization algorithm using CLS, Neumaier and Kimiaei [30, Theorem 4.2] proved a complexity of  $\mathcal{O}(\varepsilon^{-2})$  for the general case and  $\mathcal{O}(\log \varepsilon^{-1})$  for the strongly convex case for the number of iterations and function evaluations under the condition that for fixed tuning parameters  $0 < \kappa < \lambda < \infty$  the initial step sizes  $\alpha_{\text{init}}$  and the maximum step size  $\alpha_{\text{max}}$  satisfy the condition

$$\frac{\kappa |g(x)^T p|}{\|p\|^2} \leq \alpha_{\text{init}} \leq \alpha_{\text{max}} \leq \frac{\lambda |g(x)^T p|}{\|p\|^2}. \quad (14)$$

### 1.1.2 Nonlinear CG methods

In the literature, nonlinear CG methods (without preconditioner) are generally described in terms of search directions of the form

$$d^\ell = -g^\ell + \beta_{\ell-1} d^{\ell-1} \quad (15)$$

and corresponding updates

$$x^{\ell+1} = x^\ell + \gamma_\ell d^\ell, \quad (16)$$

where  $\gamma_\ell$  is a positive step size. The first nonlinear CG method, introduced by Fletcher and Reeves [14], uses (15) with

$$\beta_{\ell-1} := \frac{(g^\ell)^T g^\ell}{(g^{\ell-1})^T g^{\ell-1}}. \quad (17)$$

For a quadratic function  $f(x) = \frac{1}{2}x^T Ax - b^T x$  with symmetric positive definite Hessian  $A$ , they showed the equivalence with the CG method of Hestenes and Stiefel [22] for solving the linear system of equations  $Ax = b$ , and hence finitely terminates with  $g^\ell = 0$  for  $\ell \leq n$ .

Many other formulas for the  $\beta$ s, sharing this property, are in use. The most prominent examples are, with  $y^{\ell-1} := g^\ell - g^{\ell-1}$ ,

$$\begin{aligned}\beta_\ell^{FR} &= \frac{(g^\ell)^T g^\ell}{(g^{\ell-1})^T g^{\ell-1}} \quad (\text{Fletcher and Reeves [14]}), \\ \beta_\ell^{PR} &= \frac{(y^{\ell-1})^T g^\ell}{(g^{\ell-1})^T g^{\ell-1}} \quad (\text{Polak and Ribiere [35]}), \\ \beta_\ell^P &= \max(0, \beta_\ell^{PR}) \quad (\text{Powell [36]}), \\ \beta_\ell^{CD} &= \frac{(g^\ell)^T g^\ell}{(y^{\ell-1})^T d^{\ell-1}} \quad (\text{Fletcher [13]}), \\ \beta_\ell^{HS} &= \frac{(y^{\ell-1})^T g^\ell}{(y^{\ell-1})^T d^{\ell-1}} \quad (\text{Hestenes and Stiefel [22]}).\end{aligned}$$

Further variants can be found in the thorough survey of nonlinear CG methods by Hager and Zhang [21]. In Sect. 4, we compare two versions of our CG method with 21 CG methods from the literature [1, 2, 4, 8–10, 12, 14, 18, 22, 23, 26–28, 32, 35, 41], listed in Table 1 in Sect. 4.2.

For the optimization of quadratic functions, all these formulas are equivalent in exact arithmetic. But they have different properties in finite precision arithmetic and in generalizations to the optimization of nonquadratic functions. In particular, on non-quadratic problems, some of these formulas may exhibit convergence difficulties such as jamming, where many consecutive excessively small steps are taken. In addition, in order that the search directions generated are descent directions, restrictions on the previous step sizes are needed. The survey by Hager and Zhang [21] discusses these problems in more detail.

The survey [21] also gives derivations of the global convergence results known at the time. Almost all (cf. Section 1.1.5) previously known globally convergent nonlinear CG methods determine their step sizes  $\gamma_\ell$  by enforcing some version of the Wolfe conditions [40], thus involving gradients at each trial point.

### 1.1.3 Restart techniques

Practical CG methods use a restart strategy in which the CG direction is replaced by the steepest descent direction, to achieve a minimizer of a quadratic function after at most  $n$  iterations. Powell [37] gave three reasons why the traditional restart procedure is not good, and used a two-term CG direction instead of the steepest descent direction for restart iterations. Then, Beale [5] retained the restart procedure of Powell for restart iterations and used the three-term CG directions for non-restart iterations. Dai and Yuan [10] used these two restart procedures as an algorithm called the Beale and Powell restart algorithm, and showed by example that this algorithm may not converge. To

obtain convergence results for the Beale and Powell restart algorithm, they restricted the CG parameters (generate only positive values) and constructed a modified Beale and Powell restarted algorithm. The improved Beale and Powell restart algorithm initializes the restart counter  $t = 1$  and then updates this counter by  $t = \ell - 1$  if  $\ell - t \geq n$  or the condition

$$\left| (g^{\ell-1})^T g^\ell \right| > c_1 \|g^\ell\|_*^2 \text{ for } \ell \geq 2,$$

holds, where  $0 < c_1 < 1$ . Then, the CG direction  $d^\ell$  and the corresponding update  $x^{\ell+1}$  is computed according to whether or not restart is required:

- If  $\ell > t + 1$ , the three-terms CG direction for restart iterations

$$d^\ell = -g^\ell + \beta_\ell^{HS} d^{\ell-1} + \bar{\beta}_\ell d^t \quad (18)$$

is computed, where  $\bar{\beta}_\ell$  is  $\beta_\ell^{HS}$  with the difference that  $y^\ell = g^{\ell+1} - g^\ell$  is replaced by  $y^t = g^{t+1} - g^t$ . As long as the condition

$$-c_3 \|g^\ell\|_*^2 \leq (g^\ell)^T d^\ell \leq -c_2 \|g^\ell\|_*^2 \text{ with } 0 < c_2 < 1 < c_3 < \infty \quad (19)$$

does not hold,  $t = \ell - 1$  is chosen and  $d^\ell$  is recomputed by (18). Once the condition (19) holds,  $d^\ell$  computed by (18) is sufficiently downhill; hence the new point

$$x^{\ell+1} = x^\ell + \alpha_\ell d^\ell \quad (20)$$

is computed, where  $\alpha_\ell$  satisfies Wolfe conditions.

- If  $\ell = t + 1$ ,  $\bar{\beta}_\ell = 0$  is chosen in (18) and the two-terms CG direction  $d^\ell$  is computed by (18), regardless of whether or not the condition (19) holds, and the new point is computed by (20).

Very recently, Chan-Renous-Legoubin and Royer [7] employed a backtracking line search along several known CG directions with a nonstandard restart condition. They restarted their algorithm if at least one of the two conditions

$$(g^\ell)^T d^\ell < -c_1 \|g^\ell\|_*^{1+p}, \quad 0 < c_1 \leq 1, p \geq 0 \quad (21)$$

$$\|d^\ell\| < c_2 \|g^\ell\|_*^q, \quad c_2 \geq 1, q \geq 0 \quad (22)$$

is violated.

### 1.1.4 Hybrid conjugate gradient methods

Section 4 compares only algorithms that use exclusively CG directions. There are, however, some software packages that use CG as a basic technique, but have been enhanced with a considerable number of modifications to improve practical performance, see e.g., CG\_DESCENT of Hager and Zhang [17–19], LMBOPT [24] of Kimiaei et al. [24], ASACG of Hager and Zhang [17–20], and CGOPT of Liu et al. [25]. Most

of these solvers were comprehensively compared in [24] on the unconstrained and bound-constrained CUTEst test problems of Gould et al. [16].

### 1.1.5 Complexity for conjugate gradient methods

Cartis et al. [6] proved a complexity of  $\mathcal{O}(\varepsilon^{-2})$  for a general class of gradient-free line search algorithms along *gradient-related search directions*, defined as those satisfying the conditions

$$(g^\ell)^T d^\ell \leq -\kappa_1 \|g^\ell\|_*^2, \quad \|d^\ell\| \leq \kappa_2 \|g^\ell\|_* \quad \text{for } \kappa_1, \kappa_2 > 0. \quad (23)$$

In fact, concerning the search directions, the conditions (23) imply the bounded angle condition (9) with  $\delta = \kappa_1/\kappa_2$ , and thus, the same complexity result as their follows analogously by our Theorem 8(i) below. But, to the best of our knowledge, there is no result in the literature that any of the previously known CG formulas leads to search directions satisfying (23). Hence, their complexity analysis does not apply to CG methods.

Very recently, a complexity result for a nonlinear CG method was given by Chan-Renous-Legoubin and Royer [7]. They proved that

$$N := \mathcal{O}(\varepsilon^{-2}) + \mathcal{O}\left(\varepsilon^{-\max\{1+p, 2(1+p-q)\}}\right)$$

function evaluations are sufficient for reaching a point  $x^\ell$  with  $\|g^\ell\|_* \leq \varepsilon$ . The best complexity  $N = \mathcal{O}(\varepsilon^{-2})$  is obtained in this formula when  $p \leq \max(q, 1)$ . For  $p = q = 1$ , their restart rule guarantees that the search directions satisfy (23), and as a consequence, the analysis of Cartis et al. [6] also applies. Their family of methods also does not use the Wolfe conditions. However, compared to our method, no requirement is imposed on the factors  $\beta_{\ell-1}$  in (15), and convergence and complexity results are completely unaffected by their choice. Moreover, the restart conditions (21) and (22) may trigger a restart even when the objective function is quadratic, and the factors  $\beta_{\ell-1}$  are chosen by one of the standard formulas, thus possibly impairing the finite termination property for quadratic functions.

## 1.2 An overview of our method

The present paper analyzes a new nonlinear CG method called NCG, formally specified in Algorithm 2. Compared to the traditional approaches, we can summarize here the following new features:

- Most of the known nonlinear CG methods need for their global convergence that the (strong) Wolfe conditions at each step hold. This involves the gradient evaluation at each trial point which might be expensive from the computational point of view. Our global convergence analysis of NCG does not rely on the Wolfe conditions and uses the so-called efficient line search methods which generate step sizes satisfying (4).

- A restart condition is built into the algorithm. This guarantees global linear convergence when it converges to a strong local minimizer without impairing the finite termination property of CG iterations for strictly convex quadratic functions.
- It is known that CG methods reduce the zigzagging effect observed in the steepest descent method. We quantify this effect by defining a measure of zigzagging strength (Sect. 2.1.1). Unless a restart is made, our CG direction is the search direction minimizing the zigzagging strength. This ensures that in our CG method, zigzagging is maximally reduced.
- NCG terminates after at most  $n$  iterations for strictly convex quadratic functions.
- NCG has the optimal complexity  $\mathcal{O}(\varepsilon^{-2})$  for continuously differentiable objective function with Lipschitz continuous gradients. Moreover, it preserves the standard optimal complexity  $\mathcal{O}(\log \varepsilon^{-1})$  for strongly convex functions.

### 1.2.1 Search directions with minimal zigzagging

In each iteration, NCG uses a new nonlinear CG direction along which CLS is tried. Unlike other CG directions (cf. Hager and Zhang [21]), our CG direction minimizes a measure of zigzagging strength, the squared preconditioned distance from the previous search direction. As a consequence, the amount of zigzagging in consecutive search directions is minimized.

### 1.2.2 A restart condition guaranteeing global linear convergence

To enforce linear convergence when NCG converges to a strong local minimizer, we guarantee in Theorem 5 below the angle condition (9) using a restart procedure that decides when to replace a poor search direction by a simplified Newton direction, using a symmetric and positive definite preconditioner  $B$ .

Unlike the restart procedure of Chan-Renous-Legoubin and Royer [7], which restarts the CG algorithm when the conditions (21) and (22) are violated, our restart is performed when at least one of the two conjugacy relations (35) and (36) is significantly violated or the number  $m$  of non-restart iterations reaches  $n$ . Like Dai and Yuan [10], this ensures that no restart is performed for quadratic functions.

### 1.2.3 A new convergence analysis

The global convergence of a new nonlinear CG method is proved in Theorem 5 that, unlike traditional nonlinear CG methods that require line search methods satisfying the Wolfe condition, uses the new gradient-free line search method. The new CG method is motivated by the desire to reduce the inefficiency of line search methods due to zigzagging of search directions discussed in Sect. 1.1.2. Our search direction is therefore chosen by minimizing (Theorem 3) a preconditioned distance from the previous search direction.

### 1.2.4 A complexity bound

We prove in Theorem 8 complexity bounds on the number of iterations of NCG. We find that NCG has the same order  $\mathcal{O}(\varepsilon^{-2})$  of complexity as the CG method by Chan-Renous-Legoubin and Royer [7], and the complexity improves to  $\mathcal{O}(\log \varepsilon^{-1})$  if the objective function has only a strong minimizer and no other stationary points.

## 2 A basic nonlinear conjugate gradient algorithm

This section discusses `NCG-basic`, a basic nonlinear conjugate gradient algorithm, and its complexity and global convergence.

### 2.1 Minimal zigzagging directions

Conjugate gradient methods are well-known methods to reduce zigzagging, but without theory. Here, we define a zigzagging measure and find search directions minimizing this measure. Our new CG algorithm is based on this construction, hence will have minimal zigzagging among all CG methods.

To measure the size of vectors, we use from now on the pair of **ellipsoidal norms**

$$\|p\| := \sqrt{p^T B p}, \quad \|g\|_* := \sqrt{g^T B^{-1} g} = \|B^{-1} g\| \quad (24)$$

defined in terms of a fixed symmetric positive definite matrix  $B \in \mathbb{R}^{n \times n}$ . Using a Cholesky factorization  $B = R^T R$  and a linear transformation  $p' = R p$ ,  $g' = R^{-T} g$ , where  $R^{-T}$  denotes the transposed inverse of  $R$ , it is easy to check that these form a pair of dual norms, so that

$$|g^T p| \leq \|g\|_* \|p\|.$$

If a symmetric and positive definite preconditioner  $B$  approximating the Hessian near the starting point is available, it is sensible to measure closeness in terms of distance in the ellipsoidal norms (24) associated with  $B$ . The case without preconditioning is obtained for the identity matrix  $B = I$ , where both norms (24) become the Euclidean norm  $\|s\|_2 := \sqrt{s^T s}$ , which is its own dual.

#### 2.1.1 Zigzagging

Starting with  $x^0 = \begin{pmatrix} \xi \\ \xi \end{pmatrix}$ , the steepest descent method ( $p^\ell = -g^\ell$ ) with exact line searches applied to the optimization problem

$$\begin{aligned} \min f(x) &= (x_1 - x_2)^2 + \varepsilon x_2^2 \\ \text{s.t. } x &\in \mathbb{R}^2 \end{aligned}$$

yields the sequence

$$x^{2\ell} = \xi(1 + \varepsilon)^{-\ell} \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \quad x^{2\ell+1} = \xi(1 + \varepsilon)^{-\ell-1} \begin{pmatrix} 1 + \varepsilon \\ 1 \end{pmatrix},$$

with arbitrarily slow linear convergence as  $\varepsilon \downarrow 0$ . The reason is inefficient **zigzagging** of the search directions. Thus, linear convergence by itself is no quality criterion, and the angle condition only serves as a guard against even slower sublinear convergence behavior (see Theorem 4).

To avoid zigzagging, we propose to choose the search direction  $p$  as a vector satisfying  $g^T p < 0$  that is closest to the previous search direction  $p_{\text{old}}$ . The preconditioned distance  $(p - p_{\text{old}})^T B(p - p_{\text{old}})$  is called **zigzagging strength measure**. If this measure is small, almost no zigzagging occurs; otherwise, a large zigzagging occurs, as in the steepest descent direction.

To compare two different search directions in a meaningful way, for a sufficiently small step size  $\alpha$ , we obtain a gain in the function value of

$$f(x) - f(x + \alpha p) = -\alpha g^T p + o(\alpha).$$

Hence, the infinitesimal quality of a direction is fully characterized by

$$v := -g^T p > 0. \quad (25)$$

We therefore compare only directions with the same value of  $v$ ; this is no restriction of generality since we may rescale an arbitrary direction to match any given value of  $v$ . (In the algorithm,  $v$  will be kept fixed, except at restarts.)

**Theorem 3** Among all  $p \in \mathbb{R}^n$  with  $g^T p = -v < 0$ , the squared preconditioned distance  $(p - p_{\text{old}})^T B(p - p_{\text{old}})$  becomes minimal for

$$p = p_{\text{old}} - \lambda B^{-1} g, \quad (26)$$

where

$$\lambda = \frac{v + g^T p_{\text{old}}}{g^T B^{-1} g}. \quad (27)$$

**Proof** This optimization problem can be solved using Lagrange multipliers. We have to find a stationary point of the Lagrange function

$$L(p, \lambda) := \frac{1}{2} (p - p_{\text{old}})^T B(p - p_{\text{old}}) + \lambda (g^T p + v),$$

giving the condition  $B(p - p_{\text{old}}) + \lambda g = 0$ , hence (26) holds. The Lagrange multiplier  $\lambda$  is determined from the constraint  $g^T p = -v$ , and yields (27).  $\square$

### 2.1.2 The NCG-basic algorithm

For a search direction of the form

$$p^\ell = \rho_\ell p^{\ell-1} - \lambda_\ell B^{-1} g^\ell, \quad (28)$$

we need

$$0 < \nu := -(g^\ell)^T p^\ell = -\rho_\ell (g^\ell)^T p^{\ell-1} + \lambda_\ell (g^\ell)^T B^{-1} g^\ell,$$

hence

$$\lambda_\ell = \frac{\nu + \rho_\ell (g^\ell)^T p^{\ell-1}}{(g^\ell)^T B^{-1} g^\ell}. \quad (29)$$

For  $\rho_\ell = 1$ , this agrees with the direction derived from the zigzagging avoiding argument in Theorem 3; for  $\rho_\ell = 0$ , we get the simplified Newton direction  $-B^{-1} g^\ell$ , up to a constant factor. Thus, search directions of the form (28) look like a flexible choice.

Algorithm 1 is a basic version of NCG, called NCG-basic. As long as  $x^\ell$  is not a stationary point, NCG-basic computes the gradient at  $x^\ell$  and the  $\ell$ th search directions by (28) using the  $\ell$ th step size (29), finds the  $\ell$ th step size  $\alpha_\ell$  by any efficient line search method so that  $\alpha_\ell$  satisfies the efficiency condition (4), and computes the  $(\ell + 1)$  point  $x^{\ell+1}$  and its function value  $f_{\ell+1} = f(x^{\ell+1})$ .

---

#### Algorithm 1 NCG-basic, basic nonlinear CG method.

---

```

1: Purpose: NCG-basic finds local minimizer of a nonlinear function  $f(x)$  (or at least a stationary point)
2: Input:  $x^0$  (starting point),  $B$  (preconditioner),  $\varepsilon$  (minimum threshold for the gradient norm).
3: Requirements:  $B$  symmetric and positive definite
4: for  $\ell = 0, 1, \dots$ , do
5:   compute  $g^\ell = g(x^\ell)$ ,  $h^\ell = B^{-1} g^\ell$ , and  $\omega_\ell = (g^\ell)^T h^\ell$ ;
6:   if  $\omega_\ell \leq \varepsilon^2$ , break; end; ▷  $x^\ell$  stationary
7:   compute  $\lambda_\ell$  by (29) and  $p^\ell$  by (28);
8:   determine  $\alpha_\ell$  such that (4) holds;
9:   compute  $x^{\ell+1} = x^\ell + \alpha_\ell p^\ell$  and  $f_{\ell+1} = f(x^{\ell+1})$ ;
10: end for
11: return  $x^{\ell+1}$  and  $f_{\ell+1}$ ;

```

---

In finite precision arithmetic,  $\omega_\ell = 0$  cannot be guaranteed; instead, in line 6 of Algorithm 1 the condition  $\omega_\ell = \|g^\ell\|_*^2 \leq \varepsilon^2$  is used for a finite termination of NCG-basic.

### 2.1.3 The basic complexity and global convergence for NCG-basic

In this section, under very weak conditions, complexity for NCG-basic is proved, which implies global convergence for NCG-basic.

**Theorem 4** Let  $v > 0$  and suppose that (28) and (29) hold for all  $\ell$  with  $|\rho_\ell| \leq 1$ . Then, for these  $\ell$ ,

$$(p^\ell)^T B p^\ell - (p^{\ell-1})^T B p^{\ell-1} \leq \frac{v^2}{(g^\ell)^T B^{-1} g^\ell}. \quad (30)$$

Moreover, if NCG-basic uses an efficient line search, the number  $L$  of iterations to reach

$$\|g^L\|_* < \varepsilon \quad (31)$$

is bounded by

$$L \leq 1 + \xi \varepsilon^2 (e^{C/\varepsilon^2} - 1), \quad (32)$$

where  $\xi := \|s^0\| / |(g^0)^T s^0|$  and  $C := \frac{\bar{\gamma}}{2\beta} (f_1 - \underline{f})$ . Here  $s^0 = x^1 - x^0$  is from (5).

**Proof** By  $\sigma_\ell := |(g^\ell)^T s^\ell| > 0$ , we have

$$\begin{aligned} (p^\ell)^T B p^\ell &= \rho_\ell^2 (p^{\ell-1})^T B p^{\ell-1} - 2\rho_\ell \lambda_\ell (g^\ell)^T p^{\ell-1} + \lambda_\ell^2 (g^\ell)^T B^{-1} g^\ell \\ &= \rho_\ell^2 (p^{\ell-1})^T B p^{\ell-1} + \frac{v^2 - \left(\rho_\ell (g^\ell)^T p^{\ell-1}\right)^2}{(g^\ell)^T B^{-1} g^\ell}. \end{aligned}$$

By (29), (30) follows since  $\rho_\ell^2 \leq 1$ . In terms of the ellipsoidal norms (24), (30) reads

$$\frac{1}{v^2} \left( \|p^\ell\|^2 - \|p^{\ell-1}\|^2 \right) \leq \frac{1}{\|g^\ell\|_*^2}.$$

Since  $s^\ell = \alpha_\ell p^\ell$  and  $\sigma_\ell = \alpha_\ell v$ , we find

$$\frac{\|s^\ell\|^2}{\sigma_\ell^2} - \frac{\|s^{\ell-1}\|^2}{\sigma_{\ell-1}^2} \leq \|g^\ell\|_*^2.$$

If  $L$  is the first index with (31), we conclude that

$$\frac{\|s^\ell\|^2}{\sigma_\ell^2} - \frac{\|s^{\ell-1}\|^2}{\sigma_{\ell-1}^2} \leq \frac{1}{\|g^\ell\|_*^2} \leq \frac{1}{\varepsilon^2} \quad \text{for } \ell < L. \quad (33)$$

Summation of both sides of (33) over all steps gives

$$\frac{\|s^\ell\|^2}{\sigma_\ell^2} \leq \xi + \frac{\ell - 1}{\varepsilon^2} \quad \text{for } \ell < L.$$

Since the line search is efficient, by (4), we have

$$\frac{\bar{\gamma}}{2\beta} (f_\ell - f_{\ell+1}) = \frac{v^2}{\|p^\ell\|^2} \geq \frac{\sigma_\ell^2}{\|s^\ell\|^2} \geq \left( \xi + \frac{\ell - 1}{\varepsilon^2} \right)^{-1} = \frac{\varepsilon^2}{\ell - 1 + \xi \varepsilon^2} \quad \text{for } \ell < L. \quad (34)$$

For any  $z > 0$ , we have

$$\frac{1}{\ell - 1 + z} \geq \log \left( 1 + \frac{1}{\ell - 1 + z} \right) = \log(\ell + z) - \log(\ell - 1 + z),$$

$$\sum_{\ell=1}^{L-1} \frac{1}{\ell - 1 + z} \geq \log(L - 1 + z) - \log z = \log \left( 1 + \frac{L - 1}{z} \right).$$

Summation of both sides of (34) over all steps gives

$$\begin{aligned} \varepsilon^2 \log \left( 1 + \frac{L - 1}{\xi \varepsilon^2} \right) &\leq \sum_{\ell=1}^{L-1} \frac{\varepsilon^2}{\ell - 1 + \xi \varepsilon^2} \leq \frac{\bar{\gamma}}{2\beta} \sum_{\ell=1}^{L-1} (f_\ell - f_{\ell+1}) \\ &= \frac{\bar{\gamma}}{2\beta} (f_1 - f_L) \leq \frac{\bar{\gamma}}{2\beta} (f_1 - \underline{f}) := C, \end{aligned}$$

resulting in

$$L \leq 1 + \xi \varepsilon^2 (e^{C/\varepsilon^2} - 1).$$

□

The bound (32) is extremely weak, and will be improved under additional conditions.

Theorem 4 implies convergence.

**Corollary 1** *If NCG-basic uses an efficient line search,  $\liminf_{\ell \rightarrow \infty} \|g(x^\ell)\|_* = 0$ .*

### 3 NCG, an improved version of NCG-basic

Section 3 contains the following important features:

- In Section 3.1, Theorem 5 shows under the restart conditions (defined by (35) and (36), below) the bounded angle condition (9) can be satisfied and, as a consequence, an improved complexity for NCG can be found compared to the complexity of NCG-basic.
- In Section 3.2, the NCG algorithm is introduced and its steps is described.
- In Section 3.3, Theorem 6 shows globally linear convergence for NCG.
- In Section 3.4, a modification of CLS is introduced to find line search step sizes.
- In Section 3.5, Theorem 7 shows that the CG restart guarantees a finite termination on quadratic functions.
- In Section 3.6, Theorem 8 finds a bound on the number of iterations and function evaluations of NCG.

### 3.1 A sufficient condition for the angle condition

**Theorem 5** *Under the conditions of Theorem 4, suppose that an efficient line search is used and there are positive constants  $\kappa_1$  and  $\kappa_2$  such that, for all sufficiently large  $\ell$ , either  $p^\ell$  is parallel to the simplified Newton direction  $-B^{-1}g^\ell$  or the conditions*

$$(g^\ell)^T B^{-1} g^\ell \leq \kappa_1 (y^{\ell-1})^T B^{-1} y^{\ell-1}, \quad (35)$$

$$(y^{\ell-1})^T p^{\ell-1} \leq \kappa_2 v \quad (36)$$

hold (where  $y^{\ell-1} := g^\ell - g^{\ell-1}$ ).

- (i) *If  $\hat{x}$  is a strong local minimizer then the angle condition (9) holds for some  $\delta > 0$ .*
- (ii) *If  $f$  has a strong local minimizer  $\hat{x}$  and no other stationary point then convergence is globally linear and the number of iterations to reach a point  $x$  with*

$$\|g(x)\|_* \leq \varepsilon \quad (37)$$

*is  $\mathcal{O}(\log \varepsilon^{-1})$ . In particular, this is the case when  $f$  is strongly convex.*

- (iii) *If the initial step sizes are chosen such that (14) holds and the line search CLS is used, then the number of function evaluations needed to reach (37) is  $\mathcal{O}(\log \varepsilon^{-1})$ .*

**Proof** (i) Since the eigenvalues of a positive definite matrix are positive, the requirements on  $\hat{x}$  imply that there are positive constants  $\underline{\gamma}$ ,  $\overline{\gamma}$  and a ball  $C$  around  $\hat{x}$  such that for all  $x \in C$ , the eigenvalues of the Hessian  $\bar{G}(x)$  are in  $[\underline{\gamma}, \overline{\gamma}]$ . The remainder form of Taylor's theorem now implies that for  $x, x' \in C$ , the condition (3) and

$$\frac{1}{2} \underline{\gamma} \|x' - x\|^2 \leq f(x') - f(x) - g(x)^T (x' - x) \leq \frac{1}{2} \overline{\gamma} \|x' - x\|^2. \quad (38)$$

Interchanging  $x$  and  $x'$  in the first inequality of (38), adding the two formulas, and applying the generalized Cauchy–Schwarz inequality gives

$$\underline{\gamma} \|x' - x\|^2 \leq (g(x') - g(x))^T (x' - x) \leq \|g(x') - g(x)\|_* \|x' - x\|. \quad (39)$$

Since  $\hat{x}$  is assumed to be a strong local minimizer, relations (3) and (39) apply for  $x, x'$  sufficiently close to  $\hat{x}$ , and give

$$\underline{\gamma} \|g(x') - g(x)\|_* \|x' - x\| \leq \overline{\gamma} (g(x') - g(x))^T (x' - x).$$

Substituting  $x' = x^\ell$  and  $x = x^{\ell-1}$  and using (36), we find after division by  $\alpha_{\ell-1}$  that

$$\underline{\gamma} \|y^{\ell-1}\|_* \|p^{\ell-1}\| \leq \overline{\gamma} (y^{\ell-1})^T p^{\ell-1} \leq \overline{\gamma} \kappa_2 v$$

for all sufficiently large  $\ell$  for which (35) and (36) hold. For these  $\ell$ ,

$$\begin{aligned} (g^\ell)^T B^{-1} g^\ell \cdot (p^{\ell-1})^T B p^{\ell-1} &\leq \kappa_1 (y^{\ell-1})^T B^{-1} y^{\ell-1} \cdot (p^{\ell-1})^T B p^{\ell-1} \\ &\leq \kappa_1 \|y^{\ell-1}\|_*^2 \|p^{\ell-1}\|^2 \\ &\leq \kappa_1 \left( \bar{\gamma} \kappa_2 v / \underline{\gamma} \right)^2 = c v^2 \end{aligned}$$

for some constant  $c > 0$ . Now (30) implies

$$\frac{(p^\ell)^T B p^\ell}{v^2} \leq \frac{(p^{\ell-1})^T B p^{\ell-1}}{v^2} + \frac{1}{(g^\ell)^T B^{-1} g^\ell} \leq \frac{c+1}{(g^\ell)^T B^{-1} g^\ell}.$$

Thus,

$$\frac{v^2}{(p^\ell)^T B p^\ell \cdot (g^\ell)^T B^{-1} g^\ell} \geq \frac{1}{c+1} \quad (40)$$

for sufficiently large  $\ell$  satisfying (35) and (36). But if (35) or (36) are violated,  $p^\ell$  is the simplified Newton direction, for which (40) holds trivially by applying (28) and (29). Since  $0 < v = -(g^\ell)^T p^\ell$ , this shows that the left hand side of (9) is bounded away from zero. Hence, the angle condition (9) holds.

(ii) By (i) and Theorem 2(ii), (10) is satisfied with  $0 < q < 1$ . Thus, convergence is globally linear and at most

$$\ell = \left\lceil \frac{\log \bar{\gamma} c \varepsilon^{-1}}{\log(1/q)} \right\rceil = \mathcal{O}(\log \varepsilon^{-1})$$

iterations are required to satisfy (37).

(iii) The number  $\mathcal{O}(\log \varepsilon^{-1})$  of function evaluations is the product of the number  $\mathcal{O}(\log \varepsilon^{-1})$  of iterations and the number  $\mathcal{O}(1)$  of function evaluations of CLS (see [30, Theorem 4.1]).  $\square$

### 3.2 The NCG algorithm

Algorithm 2 describes an improved version of NCG-basic, called NCG. As long as the conditions (35) and (36) hold, Theorem 5 implies the bounded angle condition (9) holds and therefore NCG computes the search directions by the new CG direction (28). Whenever one of these two conditions does not hold, a restart process is performed to guarantee complexity for NCG.

By Theorem 3, our new search direction is not too different from the old one. Thus,  $f$  is expected to behave along the new search path like along the old one. The initial step size  $\alpha_{\text{init}}$  should satisfy the condition (14).

To start the iteration, we take  $p_{\text{old}} = 0$ . To guarantee linear convergence, we may need to reset  $p_{\text{old}}$  to zero also at suitable later stages. We call this a **restart**; the precise restart conditions used come from Theorem 5. For  $B \neq I$ , i.e., if preconditioning is used, one should store  $h^\ell := B^{-1} g^\ell$  in the computation of  $\omega_\ell := (g^\ell)^T h^\ell$ , for later use in the computation of  $p^\ell$ . Finally, by Theorem 3,  $v = -(g^\ell)^T p^\ell$  remains

**Algorithm 2** NCG, nonlinear CG method.

 8:   **if**  $\ell = 0$ ,  $\text{restart} = 1$ ;  
 9:   **else** ▷ check whether restart is required  
 10:      $\omega' = (h^\ell)^T g^{\ell-1}$ ;  
 11:      $\text{restart1} = (\omega_\ell > \kappa_1(\omega_\ell - 2\omega' + \omega_{\ell-1}))$ ;  
 12:      $\text{restart2} = (|(g^\ell)^T p^{\ell-1} + v| > \kappa_2 v)$ ;  
 13:      $\text{restart} = (\text{restart1} \text{ or } \text{restart2} \text{ or } n_{ng} \geq m)$ ;  
 14:   **end**;  
 15:   **if**  $\text{restart}$ , ▷ restart was done  
 16:     compute  $v = \omega_\ell$  and  $p^\ell = -h^\ell$ ; initialize  $n_{cg} = 0$ ;  
 17:   **else** ▷ no zigzagging CG direction  
 18:     compute  $\lambda_\ell = \frac{v + (g^\ell)^T p^{\ell-1}}{\omega_\ell}$  and  $p^\ell = p^{\ell-1} - \lambda_\ell h^\ell$ ; update  $n_{cg} = n_{cg} + 1$ ;  
 19:   **end**;  
 20:   choose the initial step size  $\alpha_{\text{init}}$  of CLS2 such that

$$\frac{\kappa |g(x^\ell)^T p^\ell|}{\|p^\ell\|^2} \leq \alpha_{\text{init}} \leq \alpha_{\max} \leq \frac{\lambda |g(x^\ell)^T p^\ell|}{\|p^\ell\|^2}; \quad (41)$$

21:   determine  $\alpha_\ell$  by CLS2 with  $x^{\ell+1} = x^\ell + \alpha_\ell p^\ell$  and  $f_{\ell+1} = f(x^{\ell+1})$ ;  
 22: **end for**  
 23: **return**  $x^{\ell+1}$  and  $f_{\ell+1}$ ;

---

constant as long as no restart is made. The result is Algorithm 2. It is a **nonlinear CG method** since by Theorem 7 below, it is for a quadratic function  $f$  with positive definite Hessian equivalent to the preconditioned CG method for solving positive definite linear systems of equations.

NCG uses a CG restart process (lines 11–13) that guarantees good complexity bounds, without impairing finite termination in the special case of quadratic functions. NCG uses the line search CLS2, a modification of CLS from [30]. CLS2 is discussed in Section 3.5. The complexity of NCG is obtained in Section 3.6.

Since in exact precision arithmetic  $\omega_\ell = 0$  is guaranteed, line 7 of Algorithm 2 uses instead the condition  $\omega_\ell = \|g^\ell\|_*^2 \leq \varepsilon^2$  for a finite termination of NCG.

NCG uses (28)–(29) with  $\rho_k = 0$  or  $\rho_k = 1$ , hence our convergence results apply.

### 3.3 Globally linear convergence of NCG

Theorem 5 implies the following global convergence result.

**Theorem 6** *The points  $x^\ell$  produced by the nonlinear CG method of Algorithm 2 satisfy (8) and in case of convergence to a strong local minimizer, the convergence is globally linear.*

Like all nonlinear CG algorithms, NCG can be implemented using very little storage only: Apart from what is needed for a Cholesky factor of the preconditioner, we need 4 vectors of storage (for  $x$ ,  $g$ ,  $p$ , and  $h = B^{-1}g$ ). Without preconditioning ( $B = I$ ), even 3 vectors suffice.

If all  $\lambda_\ell$  are positive and no preconditioning is used ( $B = I$ ), our formulas can be cast into the traditional CG form (15)–(16) if we use the scaled vectors

$$d^\ell := \lambda_\ell^{-1} p^\ell = \lambda_\ell^{-1} p^{\ell-1} - g^\ell = -g^\ell + \frac{\lambda_{\ell-1}}{\lambda_\ell} d^{\ell-1} \quad (42)$$

and the correspondence

$$\beta_{\ell-1} := \frac{\lambda_{\ell-1}}{\lambda_\ell}, \quad \gamma_\ell := \frac{\alpha_\ell}{\lambda_\ell}.$$

Thus, the two choices of search directions appear to be equivalent. However, directions of the form (28) are more flexible than directions with the traditional formula (15) since *no sign restriction* applies to the  $\lambda_\ell$ .

### 3.4 A modification of CLS

To ensure that the line search is exact and takes two function evaluations only when applied to strictly convex quadratic functions, we slightly modify the line search CLS from [30]. We call the modified version CLS2.

The only change compared to CLS is that CLS2 does not stop before the second step. Instead, it stores the function value at the first trial point and the corresponding step size. Therefore, CLS2 agrees with CLS, except that it may accept the second step size rather than the first one since it performs at least two function evaluations. Thus, all properties proved in [30] remain valid. In particular, the complexity analysis of [30, Theorem 3] still holds for CLS2.

If  $f(x + \alpha p)$  is a strictly convex quadratic, then  $\mu(\alpha) < 1$  for all  $\alpha \in \mathbb{R}$ , and the second iteration performs a quadratic interpolation step. Thus, the line search is exact and the second iteration is efficient. Therefore, CLS2 stops with exactly two function evaluations.

If  $f(x + \alpha p)$  is linear or a strictly concave quadratic, the descent direction is a direction of infinite descent, and the line search ends after extrapolations reaching  $\alpha = \alpha_{\max}$ . Thus, by general properties of CG methods, quadratic functions are minimized after at most  $n$  iterations using at most  $n$  gradient evaluations and  $2n$  function evaluations.

In detail, the difference between CLS and CLS2 consists of the following three changes:

- The initialization `firstOk = 0` is added to line 5 of CLS in line 5 of CLS2.
- Lines 7–8 of CLS are replaced by lines 7–12 of CLS2.
- Line 25 of CLS is replaced by line 29 of CLS2.

The Boolean variables `first` and `firstOk` serve to ensure that behavior is described. CLS2 initializes `first = 1` and `firstOk = 0`. If the first iteration is

---

**Algorithm 3** CLS2, curved line search.
 

---

```

1: Purpose: CLS2 finds a step size  $\alpha$  with  $\mu(\alpha)|\mu(\alpha) - 1| \geq \beta$ , and guarantees that for strictly convex
   quadratic functions, an exact line search is done.
2: Input:  $x(\alpha)$  (search path),  $f_0 = f(x(0))$  (initial function value),  $v = -g(x(0))^T x'(0)$  (directional
   derivative)
3: Tuning parameters:  $\alpha_{\text{init}}$  (initial step size),  $\alpha_{\text{max}}$  (maximal step size),  $\beta \in ]0, \frac{1}{4}[$  (parameter for
   efficiency),  $Q > 1$  (factor for extrapolation and interpolation)
4: Requirements:  $v > 0$ ,  $0 < \alpha_{\text{init}} \leq \alpha_{\text{max}} \leq \infty$ 
5: Initialization:  $\text{first} = \text{false}$ ;  $\text{firstok} = \text{false}$ ;  $\underline{\alpha} = 0$ ;  $\bar{\alpha} = \infty$ ;  $\alpha = \alpha_{\text{init}}$ ;
6: while 1 do
7:   compute  $f_a = f(x(\alpha))$  and the Goldstein quotient  $\mu(\alpha) = (f_0 - f_a)/(\alpha v)$ ;
8:   if  $\mu(\alpha)|\mu(\alpha) - 1| \geq \beta$ , ▷ sufficient descent condition was satisfied
9:     if  $\text{first}$ ,  $\alpha_1 = \alpha$ ;  $f_1 = f_a$ ; else, break; end
10:     $\text{firstok} = \text{true}$ ;
11:  end
12:  if  $\text{firstok}$  and not  $\text{first}$ ,  $\alpha = \alpha_1$ ;  $f_a = f_1$ ; break; end
13:  if  $\mu(\alpha) > \frac{1}{2}$ ,  $\underline{\alpha} = \alpha$ ;
14:  elseif  $\alpha = \alpha_{\text{max}}$ , break;
15:  else, set  $\bar{\alpha} = \alpha$ ; ▷ linear decrease or more
16:  end
17:  if  $\text{first}$ , ▷ initially check whether function is almost quadratic or not
18:     $\text{first} = \text{false}$ ;
19:    if  $\mu(\alpha) < 1$ ,  $\alpha = \frac{1}{2}\alpha/(1 - \mu(\alpha))$ ; else  $\alpha = \alpha Q$ ; end
20:  else
21:    if  $\bar{\alpha} = \infty$ , expand to  $\alpha = \alpha Q$ ; ▷ extrapolation was done
22:    elseif  $\underline{\alpha} = 0$ , compute  $\alpha = \frac{1}{2}\alpha/(1 - \mu(\alpha))$ ; ▷ interpolation was done
23:    else, calculate  $\alpha = \sqrt{\underline{\alpha}\bar{\alpha}}$ ; ▷ geometric mean was computed
24:    end
25:  end
26:  restrict  $\alpha = \min(\alpha, \alpha_{\text{max}})$ ;
27:  end
28: end while
29: return  $\alpha$  and  $f_a$ ;
    
```

---

efficient, `firstok` is changed to true. On the next iterations, `first` is then changed to false. The Boolean variable `first` ensures that the quadratic case is handled optimally, and the Boolean variable `firstok` ensures that the line search is terminated in the second iteration if the first iteration is efficient, but the second iteration is inefficient. In this case, the values of the first iteration are restored.

### 3.5 Finite termination on quadratics

Our motivation for the CG restart is to guarantee a finite termination on quadratic functions. Theorem 7 below shows that in exact precision arithmetic, Algorithm 2 for quadratic functions terminates after at most  $n$  gradient evaluations with a minimizer or with a direction of infinite descent, though in finite precision arithmetic, it may take more than  $n$  gradients evaluations and  $2n$  function evaluations to find such a minimizer.

**Theorem 7** *Applied to quadratic functions*

$$f(x) = \gamma + c^T x + \frac{1}{2} x^T G x, \quad (43)$$

Algorithm 2 for  $m \geq n$  performs no restarts and produces the same sequence of  $x^\ell$  as the nonlinear CG method by Fletcher and Reeves. In particular, Algorithm 2 stops for quadratic functions after at most  $n$  iterations with a minimizer or with a direction of infinite descent.

**Proof** We have

$$p^\ell = p^{\ell-1} - \lambda_\ell B^{-1} g^\ell, \quad x^{\ell+1} = x^\ell + \alpha_\ell p^\ell.$$

For a quadratic function (43), we have  $g^\ell = c + Gx^\ell$ , hence

$$g^\ell - g^{\ell-1} = G(x^\ell - x^{\ell-1}) = \alpha_{\ell-1} G p^{\ell-1}.$$

For quadratic functions, CLS2 becomes exact, hence

$$\alpha_\ell = \frac{-(g^\ell)^T p^\ell}{(p^\ell)^T G p^\ell} = \frac{\nu}{(p^\ell)^T G p^\ell}$$

as long as no restarts are made. Now  $\nu = -(g^{\ell-1})^T p^{\ell-1}$ , hence

$$\lambda_\ell = \frac{(g^\ell - g^{\ell-1})^T p^{\ell-1}}{\omega_\ell} = \frac{\nu}{\omega_\ell} > 0, \quad \beta_{\ell-1} = \frac{\lambda_{\ell-1}}{\lambda_\ell} = \frac{\omega_\ell}{\omega_{\ell-1}}.$$

Since an exact line search is used, the result of the algorithm is the same for an arbitrary rescaling of the search direction. Thus, we may rewrite the iteration in terms of the  $d^\ell$  computed by (42) and get for  $B = I$  equivalence with the Fletcher-Reeves CG method. Fletcher and Reeves [14] showed the equivalence with the CG method of Hestenes and Stiefel [22] for solving the linear system of equations  $g(x) = c + Gx = 0$ . They proved the well-known conjugacy properties

$$(g^\ell)^T p^k = (g^\ell)^T B^{-1} g^k = 0 \quad \text{for } k \leq \ell - 1,$$

which imply that given the restrictions  $\kappa_1, \kappa_2 > 0$ , no restarts will be made for  $\ell \leq m$ .

Hestenes and Stiefel showed that for positive definite  $G$ , their algorithm stops after at most  $n$  iterations with a solution of the linear system, hence with the minimizer of  $f(x)$ . If  $G$  is not positive definite, the algebra remains the same, except that it is now possible that a line search ends with a direction of infinite descent. Thus, if  $m \geq n$ , our CG method for quadratic functions after at most  $n$  iterations with a minimizer or with a direction of infinite descent.

The case with a preconditioner is easily reduced to the case  $B = I$  by means of a linear transformation of the vector  $x$  of variables; hence the same properties hold for any symmetric and positive definite  $B$ .  $\square$

Since locally all twice continuously differentiable functions are well approximated by a quadratic, the final remark in the proof also holds locally for general  $C^2$ -functions with CLS. Thus, close to a strong local minimizer, Algorithm 2 shares the excellent local convergence behavior of the quadratic case. The latter is surveyed in Axelsson and Lindskog [3] of the preconditioned linear CG method.

In particular, when a good starting point is available, no restarts are made. Far away from a minimizer, however, a strong deviation from quadratic behavior may cause a restart. In particular, whenever very little progress is made while the gradient is still large,  $g^\ell \approx g^{\ell-1}$ , hence  $y^{\ell-1} \approx 0$ , and a restart is made. Thus, jamming, a problem for the standard implementation of the nonlinear CG method by Fletcher and Reeves [14] is not possible.

### 3.6 Complexity of NCG

The following complexity result for NCG yields a bound on the number of iterations (= number of gradient evaluations) and function evaluations of NCG. Our result also holds for  $m = \infty$ , where no restart is imposed after a fixed number of iterations. But the numerical results in Sect. 4 show that setting  $m = \infty$  reduces the efficiency and robustness of NCG.

**Theorem 8** *Given constants  $0 < \kappa < \lambda < \infty$  and  $0 < m \leq \infty$ , suppose that the initial step sizes are chosen such that (14) holds. Then,*

- (i) *The number of function values needed by NCG to reach a point  $x$  with (37) is  $\mathcal{O}(\varepsilon^{-2})$ .*
- (ii) *If the sublevel set  $\{x \in \mathbb{R}^n \mid f(x) \leq f(x^0)\}$  is bounded then, starting with  $x^0$ , at least one subsequence of the points generated by NCG converges to a stationary point.*
- (iii) *If  $f$  has a strong local minimizer  $\hat{x}$  and no other stationary point then convergence is globally linear and the number of function values needed by NCG with  $m \geq n$  to reach a point  $x$  with (37) is  $\mathcal{O}(\log \varepsilon^{-1})$ . In particular, this is the case when  $f$  is strongly convex.*

**Proof** (i) Denote by  $R$  the index set of restart iterations and by  $R^c$  the index set of non-restart iterations. For  $\ell \in R$ , the search direction  $p^\ell = -B^{-1}g^\ell$  satisfies the bounded angle condition (9) since

$$(g^\ell)^T p^\ell = -(g^\ell)^T B^{-1} g^\ell = -\|g^\ell\|_*^2, \quad \|p^\ell\| = \sqrt{(p^\ell)^T B p^\ell} = \sqrt{(g^\ell)^T B^{-1} g^\ell} = \|g^\ell\|_*;$$

hence

$$\frac{((g^\ell)^T p^\ell)^2}{\|p^\ell\|^2} \geq \delta^2 \|g^\ell\|_*^2 \quad \text{for } \ell \in R. \quad (44)$$

Denote  $f_\ell := f(x^\ell)$  and  $f_{\ell+1} := f(x^\ell + \alpha_\ell p^\ell)$ , and suppose that the algorithm ends at  $x^L$  with

$$\|g(x^L)\|_* < \varepsilon \leq \|g(x^\ell)\|_* \quad \text{for } \ell < L. \quad (45)$$

We now find an upper bound on the number  $L$  of iterations of NCG. Substituting (44) into (4), we obtain

$$f_\ell - f_{\ell+1} \geq \frac{2\beta}{\gamma} \delta^2 \|g(x^\ell)\|_*^2 \geq \frac{2\beta}{\gamma} \delta^2 \varepsilon^2 \quad \text{for } L > \ell \in R. \quad (46)$$

For  $\ell \in R^c$ , we have  $f_\ell - f_{\ell+1} > 0$  and so  $\sum_{\ell \in R^c} (f_\ell - f_{\ell+1}) > 0$ . Hence, (2) and (46) imply

$$f_0 - \underline{f} \geq f_0 - f_L = \sum_{\ell=0}^{L-1} (f_\ell - f_{\ell+1}) = \sum_{\ell \in R} (f_\ell - f_{\ell+1}) + \sum_{\ell \in R^c} (f_\ell - f_{\ell+1}) \geq \frac{2\beta}{\gamma} \delta^2 \varepsilon^2 |R|,$$

leading to

$$|R| \leq C \varepsilon^{-2} \quad \text{with } C := \frac{\bar{\gamma}(f_0 - \underline{f})}{2\beta\delta^2}.$$

Since  $|R^c| \leq m|R|$ , this proves

$$L = |R| + |R^c| \leq (m+1)|R| \leq (m+1)C\varepsilon^{-2}.$$

By [30, Theorem 4.1], the number of function evaluations of CLS2 in each iteration is bounded by a constant. Therefore, this also holds for CLS2. Hence, the number of function evaluations of NCG is  $\mathcal{O}(L) = \mathcal{O}(\varepsilon^{-2})$ .

(ii) By (i),  $\inf_{\ell \geq 0} \|g(x^\ell)\|_* = 0$ , which together with a standard compactness argument gives the result.

(iii) follows directly from Theorem 5(iii).  $\square$

## 4 Numerical results

In this section, we compare our algorithm NCG with the CG methods listed in Table 1 on all 507 unconstrained test problems with dimensions 2 to 9000 from the CUTEst collection by Gould et al. [16].

NCG is Algorithm 2 with the new CG direction and the tuning parameters

$$\kappa_1 = 1, \kappa_2 = 10, \kappa = 10^{-10}, \lambda = 10^{-2}, m = 2n + 10, l_{\max} = 20, \beta = 0.02.$$

To have a fair comparison, the preconditioner  $B$  was chosen an identity matrix in the NCG algorithm. The initial step size for CLS in the  $\ell$ th iteration of NCG was computed by

$$\alpha_{\text{init}} = \max(\kappa\alpha_0^\ell, \min(\alpha_h^\ell, \lambda\alpha_0^\ell)) \quad \text{with } \alpha_0^\ell = |(g(x^\ell))^T p^\ell| / \|p^\ell\|^2,$$

satisfying the condition (41). Here, the  $\ell$ th heuristic step size  $\alpha_h^\ell$  was computed heuristically as in `goodStep` of the LMBOPT solver by Kimiaei et al. [24]. We also compare this default NCG with NCG-, which stands for NCG with  $m = \infty$ .

To compute the CG parameter  $\beta_k$ , most CG methods need the curvature condition to guarantee that the condition  $d_k^T y_k > 0$  holds for the nonconvex functions since this condition appears in  $\beta_k$ . Here  $d_k$  is computed by (15) and  $y_k = g_{k+1} - g_k$ . Except for NCG and NCG–, all CG methods tested use along the CG directions the strong Wolfe line search `cvsrch` by Moré and Thuente [33], with the default values for its tuning parameters.

Since the global convergence of CG methods is only guaranteed using line searches, the efficiency and robustness of CG methods depend on the line search strategy employed. Therefore, to avoid biased comparisons, one must incorporate CG directions with line search strategies that are competitive in terms of efficiency and robustness. While most of the known CG methods require the Wolfe conditions to ensure convergence, our CG method achieves global convergence for any line search satisfying condition (4). Neumaier and Kimiaei [30] conducted a comprehensive numerical comparison between CLS and three different line search methods: Wolfe,

Armijo, and Goldstein. According to their numerical experiments, CLS2 emerged as competitive with the Wolfe line search and showed superiority over the other two line search strategies. Specifically, CLS is notably more efficient in terms of gradient evaluations compared to the Wolfe line search, while the Wolfe line search is more efficient than CLS in terms of the number of function evaluations. Since known CG methods rely on the Wolfe conditions, and NCG requires CLS to ensure convergence, we incorporate CLS2 for our CG method and use the Wolfe line search for the remaining CG directions in our comparison.

For numerical comparison, we restrict ourselves here only to pure CG algorithms listed in Table 1 below. Ignoring practical improvements in these pure algorithms, the two most robust algorithms NCG and DL+ solve 77% of the CUTEst test problems (see Table 1 below). The CG solvers using several practical improvements can solve most of test problems. For example, as can be seen from [20, 24], LMBOPT [24, Table 1] using our CG formula solved 88% of the CUTEst test problems and ASACG [20] using a traditional CG formula solved 86% of those problems.

#### 4.1 Efficiency and robustness

We denote by  $\mathcal{S}$  the list of compared solvers, by  $\mathcal{P}$  the list of problems, and by  $c_{p,s}$  the cost measure of the solver  $s \in \mathcal{S}$  to solve the problem  $p \in \mathcal{P}$ . Our cost measures are the number  $\text{nf}$  of function evaluations, the number  $\text{ng}$  of gradient evaluations,  $\text{nf}2\text{g} = \text{nf} + 2\text{ng}$ , and times  $\text{sec}$  in second.

To find the approximate local minimum of the unconstrained problems, we say that a CG method is most *efficient* if it has a lowest cost measure and is most *robust* if it has the highest number of solved problems compared to the other compared CG methods on unconstrained test problem from the CUTEst collection.

Using these cost measures, the efficiency and robustness of CG methods can be identified by performance profile of Dolan and Moré [11]. The performance profile of the solver  $s$

$$\rho_s(\tau) := \frac{1}{|\mathcal{P}|} \left| \left\{ p \in \mathcal{P} \mid pr_{p,s} := \frac{c_{p,s}}{\min(c_{p,\bar{s}} \mid \bar{s} \in \mathcal{S})} \leq \tau \right\} \right|. \quad (47)$$

is the fraction of problems that the performance ratio  $pr_{p,s}$  is at most  $\tau$ . In particular, the fraction of problems that the solver  $s$  wins compared to the other solvers is  $\rho_s(1)$  and for sufficiently large  $\tau$  the fraction of problems that the solver  $s$  can solve is  $\rho_s(\tau)$ .

A problem is considered **solved** if  $\|g\|_\infty \leq 10^{-6}$ , while it is considered **unsolved** if either the number of function values plus twice the number of gradient evaluations reaches  $20n + 10^4$  or time in seconds reaches 300 s. These termination criteria are given in the first row of Table 1 below. Hence, each algorithm was terminated once one of the three proposed termination criteria was satisfied. These impose upper bounds on  $\|g\|_\infty$ ,  $\text{sec}$ , and  $\text{nf}2\text{g}$ . For a given list  $S$  of solvers and each given cost measure  $c_s$ , the **partial efficiency**

$$e_{s,p} := \begin{cases} 1/pr_{p,s} & \text{if the solver } s \text{ solves the problem } p, \\ 0 & \text{otherwise} \end{cases}$$

of the solver  $s$  measures the strength of the solver  $s$  relative to an ideal solver corresponding to the best solver for the problem  $p$  in percent, rounded to integers. The **efficiency**  $e_s$  of the solver  $s$  to solve all  $p \in P$  is the sum of  $e_{s,p}$  over  $p \in P$ . The efficiency with respect to the cost measures  $\text{nf}$ ,  $\text{ng}$ ,  $\text{nf2g}$ , and  $\text{sec}$  are called *nf efficiency*, *ng efficiency*, *nf2g efficiency*, and *sec efficiency*, respectively. The other columns of the table contain the number of solved problems by the solvers, the  $\text{nf2g}$  efficiency, the  $\text{ng}$  efficiency, the  $\text{nf}$  efficiency, and the  $\text{sec}$  efficiency. When using reverse automatic differentiation, the cost of a gradient evaluation is a small multiple of the cost of a function evaluation. For the CUTEst collection, this factor is on the

**Fig. 1** The performance profiles in terms of  $\text{nf}$ ,  $\text{ng}$ ,  $\text{nf2g}$ , and  $\text{sec}$  for 6 more robust CG methods. Problems solved by no solver are ignored. All compared solvers used the budgets  $\text{secmax} = 300$  and  $\text{nfmax} = 20n + 10000$

average approximately 2; see Sect. 3 of the supplemental material of the LMBOPT [24], available at <https://doi.org/10.5281/zenodo.5607521>.

If gradients are computed by finite differences the appropriate cost measure would be  $\text{nf} + n * \text{ng}$ , which would favor even more methods using few gradients.

## 4.2 A comparison of CG methods

Table 1 and the performance profiles of Fig. 1 summarize the results of our numerical experiments. We see that due to restarts after a suitably fixed finite number of iterations, NCG is slightly more robust and efficient than NCG-. In the following analysis, we therefore ignore NCG-, and compare NCG with the other 21 CG methods from Table 1.

By inspecting the results, we may conclude that

- NCG, DL+, FA, NYF, and MBA are most robust among all compared CG methods. Hence, in terms of robustness NCG is competitive with the best state-of-the-art CG methods.
- In terms of the ng efficiency, NCG is most efficient since it is 23% more efficient than the second best method DL+.
- In terms of the nf efficiency, DL+ is most efficient since it is 5% more efficient than the second best method NCG.
- In terms of the nf2g efficiency, NCG is 11% more efficient than the second best method DL+.
- In terms of the sec efficiency, DL+ and DK+ are 12% more efficient than NCG.

## 5 Conclusion

This paper proposes a new nonlinear CG algorithm (NCG) for unconstrained optimization problems. The global convergence of NCG has been obtained without enforcing the strong Wolfe conditions but rather using an arbitrary efficient line search method that does not use any gradient evaluations. A restart condition ensures global linear convergence if it converges to a strong local minimizer without affecting the finite termination for strictly convex quadratic functions. Unless a restart is made within NCG, zigzagging is maximally reduced based on an introduced zigzagging strength.

It has been shown that NCG needs at most  $\mathcal{O}(\varepsilon^{-2})$  function evaluations to find a  $\varepsilon$ -stationary point. This complexity result reduces to  $\mathcal{O}(\log \varepsilon^{-1})$  provided that  $f(x)$  has a strong local minimizer and no other stationary point.

Our numerical results on the 507 unconstrained CUTEst test problems illustrate that NCG is competitive with the best state-of-the-art CG methods in terms of the robustness and efficiency.
